#### CERTIFICATION

This is to certify that I have received an accounting from MULLIRA Sub-project # 133 for the period 1 September 1964 - 30 April 1965. The accounting reflects expenses in the amount of \$307.88 for the remaining grant balance.

The accounting statement and payment certification will be retained by TSD and will be made available for review in TSD if necessary.

I certify that satisfactory services represented by the accounting have been received and that to the best of my knowledge and belief the funds expended were for the purposes authorized by the project approval.

Chief, TSD/BB

133-16 12 October 1964 to acknowledge the extension of the expiration Word of the extension was date of transmitted to me via telephone by on 12 October 1964. The current balance on account 440.11 is \$307.88. This sum will be used for payment of publication costs of a paper in SCONOMIC GEOLOGY and the remainder for the purchase of expendable laboratory items. Thank you for permitting this and extension. Sincerely yours cc Research Division Comptroller #133

19 October 1964

133-17

MEMORANDUM FOR : Calef, Covert Claims Branch

SUBJECT ----

: MKULTRA Subproject 133

Attached are certifications from Chief, Biological Branch, for MOLTRA Subproject 133 Invoices 2 and 3 and should be recorded in account 760.

/S 1 9 OCT 1964

Distribution: Original & 1 - Addressee

s 1 m 133-18 6-20 October 12, 1964 In response to your letter of October 8, attached please find an accounting of prove funds provided for casearch performed under the direction of the period beginning September 1, 1962 and ending August 31, 1964. We trust that the report is sufficiently detailed for your purposes. Please advise what disposition should be made of the unexpended balance of \$307.88. Very truly yours Assistant to the Comptroller enclosure

PROJECT CRYPTO

: MKULTRA # 133

PRINCIPAL INVESTIGATOR

DATE RENEWED : 29 July 1963

During the previous year concentrated his efforts on the elucidation of mechanisms of microbial action on mineral sulfides and manganese nodules.

Bacterial dissolution of  $As_2S_3$ ,  $FeS_2FeAs_2$ , and  $3Cu_2SAs_2S_5$ was demonstrated. The end products were shown to be arsenite, arsenate,  $Fe^{#}$ ,  $Fe^{#T}$ , and  $Cu^{#T}$ , with the fate of the sulfur still undetermined.

Studies on CuS2 indicated that Thiobacillus sp. were unable

to solubilize this mineral in pure culture. They found that dissolution of this mineral under natural conditions necessitated the presence of protozoa and fungi. These organisms were all active under conditions of copper concentration which would normally be lethal.

Samples of manganese nodules collected by in were the Atlantic Ocean (as a guest of a studied to determine the nature of possible bacterial transformations. A preliminary scheme for this activity was determined to be a non-biological dismutation Mn# and MnO2 forming Mn#. This latter ion must be stabilized and it is likely that organic by-products of bacterial metabolism play this role.

characteristics for application to the power source studies

During the present year methods for mass culture of mineral oxidizers have been developed which will furnish cell material for enzymatic and resting cell studies. Continued work on manganese transformations is emphasizing environ mental effects.

Attachment: Proposal

Distribution: Original Only

Proposal No. entitled C for renewal of for the period 1 September 1963 - 31 August 1964 Submitted on behalf of April\_1963

PURPOSE OF STUDY

This proposal is a request for renewal for the period 1 September 1963-31 August 1964 of the grant-in-aid presently supporting research on The field of investigation covered by the present grant is so broad and relatively unexplored that several additional years of research can be profitably spent in unraveling the problem. The results of the research carry increasing significance not alone academically but also practically, as in public health, conservation of mineral resources, mineral exploration, and mineral extraction. In public health, these investigations are providing clues to the possible origin and control of acid ferruginous, and/or acid cupriferous, and/or acid arsenical stream pollution, deriving from bacterial action on natural mineral deposits in certain geographical locations1, With continued population increase, maintenance of all water resources in a condition fit for human consumption becomes more and more important. The work is also providing additional clues to the understanding of manganese biochemistry in public water supplies, where manganese together with iron can causediscoloration of water and water containers, and where manganese and iron are deposited biologically in water mains and pipes. In the area of conservation of mineral resources, the work under con- provides a basis for assessing and controlling any relative instability of mineral deposits in relation to microbes. It seems evident that uncontrolled bacterial leaching could conceivably lead to depletion and eventual complete translocation of some deposits. In mineral emploration, this work indicates that special groups of microorganisms known to be able to live at the expense of a specific mineral may be of great assistance in discovering new sites of minoral deposits. Finally, this work lends additional support to the practice of using microbes in mineral extraction.

123-2

SUMMARY OF WORK ACCOMPLISHED UNDER THE 1962-63

(a) Microbial Action on Mineral Sulfides

Quantitative studies on the action of the <u>Thiobacillus-Ferrobacillus</u> group of bacteria on the minerals orpiment  $(As_2S_3)$ , arsenopyrite  $(FeS_2FeAs_2)$ , and enargite  $(3Cu_2SAs_2S_3)$ , were initiated. The bacteria achieved significant solubilization of orpiment, releasing arsenic as arsenite and arsenate. Oxidation of the sulfur portion of orpiment is probable, but remains to be experimentally verified. Some spontaneous, nonbiological oxidation of orpiment occurred, but it was only about one-third as extensive as with bacteria. The chemistry of bacterial oxidation of orpiment appears to differ significantly from nonbiological oxidation as reflected by pH changes during the processes, With bacteria the pH fell from 3.5 to 2.0 in thirty-five days, but without bacteria it rose from 3.5 to 5.0 in that time. The precise chemical mechanism of orpiment oxidation remains to be worked out.

FROM

133-21

Quantitative work on bacterial oxidation of arsenopyrite showed release of iron, arsenic, and probably sulfur, from the mineral. Most of the analyses in this study were carried out by an undergraduate student for his senior thesis. The results have shown that, contrary to a sustained release of soluble arsenic from orpiment by bacteria, only a limited amount of soluble arsenic was released by them from arsenopyrite. This happened in spite of a pronounced release of iron. The reason for limited release of soluble arsenic by bacteria from arsenopyrite is the precipitation of iron arsenites and arsenates after a critical concentration of soluble iron and arsenite and arsenate has been reached. Although some oxidation of arsenopyrite occurred in the absence of bacteria, its extent was less and its chemistry different, because iron arsenates and arsenites were not precipitated without bacteria, and the pH of the medium dropped from 3.5 to 2.5 in thirty-six days with bacteria and rose from 3.5 to 4.0 in that time without bacteria. The extensive reprecipitation of iron and arsenic through bacterial action has direct implications with respect to possible translocation of the constituents of arsenopyrites in nature. The bacterial phenomenon also poses a problem when arsenic and iron are to be extracted together from a natural mineral deposit.

133-2

Quantitative work on bacterial oxidation of enargite has given results resembling those with arsenopyrite. Although the bacteria are evidently acting on the mineral, a sustained solubilization of the component arsenic is not noted. Indeed, in the presence of bacteria the dissolved arsenic concentration drops after an initial rise. In the absence of bacteria the arsenic concentration rises slightly but continually. It is not clear from the results so far what the fate of the arsenic or copper is after bacterial action because no recognizable precipitate was formed. Contaminating iron is released extensively by bacteria from the mineral but not without them. The released iron appears to remain in the ferrous state. The pH changes are from 3.5 to 2.5 with bacteria, and from 3.5 to 4.5 without bacteria, in thirty-six days. A precise description of the chemical changes that enargite undergoes remains to be worked out.

Growth on cuprous sulfide by the Thiobacillus-Ferrobacillus group, investigated chiefly by a graduate student, is showing variable responses on different synthetic preparations. Bacterial enrichment cultures derived from several mine effluents during the past year have, however, given more consistent growth responses on these preparations. The possibility arises that consistent action on cuprous sulfide requires the participation of more than one organism. In this connection, the principal investigator found protozoa and fungi accompanying the <u>Thiobacillus</u>-Ferrobacillus group of bacteria in mine water from the principal investigator found protozoa and fungi accompanying the companying the protozoa included an amoeba and a flagellate, which appeared to grow at the expense of the bacteria and fungi. The amoeba were observed to ingest such organisms. Both kinds of protozoa are unusual in their tolerance of 800 ppm copper and upwards of 2000 ppm iron. Ordinarily these metal concentrations would be expected to be lethal. The flagellate has been repeatedly subcultured in an iron-salts medium in mixed culture with the Thiobacillus-Ferrobacillus group of bacteria.

## (b) Manganese Nodules

During three cruises in the Atlantic Ocean in June, July, and August, thirty-four manganifer-1962, as guest of the the second second ous samples and twenty-four\_cores\_of bottom deposits were taken. About two-thirds of the manganiferous samples have now been tested for their bacterial content and for the ability of these bacteria in aiding manganese addition to the respective Most of these samples were also anasamples, as previously described by lyzed for total iron and manganese content. The results showed that the various manganiferous samples were by no means alike, In some cases this was obvious by visual inspection. In other cases, however, the differences were not macroscopically apparent. Instead, the iron-manganese content, or the bacterial content, or the Mn adsorptive power of the samples, showed differences. Results of experiments, designed to test for the enhancement of Mn adsorption by manganiferous material with the help of the native bacterial flora, could be divided into four major categories. In one, bacterial enhancement of Mn adsorption occurred with or without prior surface-sterilization. In a second, it occurred only with surface sterilization, and in a third only without it. In a fourth, bacterial enhancement of Mn adsorption was not noted under either condition. Since not all bacteria\_from\_Mn\_nodules\_can\_ enhance Mn adsorption, inclusion of surface-sterilization in the procedure causes selection of different types of organisms from the nodule flora than omission of surface-sterilization. However, the full explanation for the variability of bacte. rial enhancement of Mn adsorption is more complicated than that. With a number of

133-2

samples it was noted that Mn uptake by manganiferous material resulted in a net loss of manganese from the adsorber. The reaction accounting for this phenomenon is the result of a dismutation between Mn<sup>2+</sup> and MnO<sub>2</sub> and will be discussed further below. This reaction was exhibited by about one-sixth of the samples tested and shows that the properties of these samples are different from the rest. It can therefore be concluded that chemical and physical properties of manganiferous materials help to determine the effectiveness of bacteria in enhancing Mn adsorption. Moreover, since all but one of the samples of the 1962 collection came from extinct submarine volcances (sea mounts), and since quite a few of these samples behaved differently from earlier samples from other sources, it is postulated that geographic location of manganiferous samples may affect their chemical, physical, and biological properties.

133-25

A clue to the nature of nonbiological Mn release from manganiferous samples is provided by an experiment which shows a dismutation reaction between Mn<sup>2+</sup> and MnO<sub>2</sub> forming Mn<sup>3+</sup> when nodules adsorb Mn<sup>2+</sup>, on the condition that Mn<sup>3+</sup> is stabilized so as to prevent it from undergoing the reverse reaction. Pyrophosphate was found to be an effective stabilizer. Since pyrophosphate does not occur in a marine environment, protein or amino acids may serve instead as stabilizors. Nodule breakdown can thus be accomplished biologically with sugar as the reducing agent of MnO<sub>2</sub>,<sup>2</sup> or nonbiologically by a dismutation reaction between Mn<sup>2+</sup> and MnO<sub>2</sub>. Why the latter reaction occurs with only some nodules, even though all have MnO<sub>2</sub> and adsorb Mn<sup>2+</sup>, remains to be explained.

The ability of <u>Arthrobacter to aid in Mn addition to nodular substance</u> was shown in pure culture experiments. From similar tests it could be concluded that <u>Vibrio</u> can similarly aid in Mn addition, but not <u>Achromobacter</u>. All three organisms have been found in nodules. <u>Arthrobacter</u>, at high peptone concentrations, causes clumping and heaping of nodular material; not so at low peptone concentrations. A similar phenomenon has been noted in soil. The clumping and heaping seems to reduce surface area, and therefore slows adsorption of Mn.

Initial experiments have revealed that <u>Arthrobacter can aid in Mn ad</u>sorption by "synthetic" MnO<sub>2</sub>. However, the adsorption and incorporation process of Mn<sup>2+</sup> is not permanent. The previously cited dismutation reaction seems to come into play eventually, probably when the bacteria become physiologically inactive at the end of their growth cycle. "Synthetic" MnO<sub>2</sub> is a much poorer adsorbent than nodule material. It is postulated that the iron in nodule material helps to stabilize the manganese in it and, for as yet unknown reasons, increases its adsorptive power.

133-2

The core samples of bottom deposits, collected last summer, were examined by enrichment for bacterial content. The distribution of bacteria in these cores was not uniform, nor were the bacteria necessarily of the same kind at different depths in the same core. These findings are similar to those cited by Zo Bell<sup>4</sup>. Work is presently under way to test the ability of the core samples to adsorb Mn with and without bacterial growth. Differences in Mn adsorptive capacity seem to exist among cores on the basis of tests so far. Such differences, if corroborated by further tests, must reflect upon Mn distribution in the sea and upon nodule distribution and structure.

PROGRAM OF FUTURE WORK

(a) Mineral Sulfides

Although it is the intention to continue testing other mineral sulfides for susceptibility to attack by the <u>Thiobacillus-Ferrobacillus</u> group, special attention will be paid to the details of bacterial action on orpiment, arsenopyrite, and enargite. Quantitative methods have to be developed for determining the proportions of various forms of a given element dissolved and reprecipitated after bacterial action. Such information should provide clues to the mechanism of action by the bacteria. The detailed information on the fate of arsenopyrite and enargite, when available, will provide information concerning the effect of side reactions on the overall process of bacterial mineral oxidation. Ultimately, it is hoped to develop methods of mass culture of a desired organism on a particular mineral to get enough cell material for resting cell studies and enzymatic investigations.

(b) Manganese Nodules

Two aims will be followed experimentally in this work. One is the further elucidation of environmental relationships to the process of nodule development or degradation. The second is the elucidation of the blochemical mechanism whereby Mm is added to, or released from, manganese nodules by bacteria. To attain the first aim, samples from various known scurces will be studied in respect to physical, chemical, and biological properties, and ettempts will be made to correlate the results with geographic location. In studying the manganese fixing capacity of bottom muds, possible correlation with nodule development will be scupht. To attain the second aim, further studies with purified cultures from nodules will be made on nodule material and on synthetic MnO<sub>2</sub> to compare and contrast behavior. Since previous experiments have already shown a difference in action by bacteria between nodule material and MnO<sub>2</sub>, a condition is provided to compare the effect of iron on the two systems. It is planned to develop more specific assay procedures for

differentiating the various exidation states of Mn and thereby to follow the exact fate of adsorbed or desorbed Mn, and to establish more clearly the role bacteria play in this process. The ultimate goal is to study the bacterial action on manganese on an enzymic level.-FOR 1962-63 FUBLICATIONS ARISING OUT OF THE WORK UNDER THIS 入 (1) (2) () (3) (4) (5) It is enticipated that a paper will be written for submission to Appl. Microbiol. on the work with manganese nodules during the last year. PERSONNEL FOR 1963-64= Associate Professor of Principal Investigator: C. Biology Technician: Graduate Student:

133-33 DEPARTMENT OF BIOLOGY June 14, 1962

#### Purpose of Study:

The purpose of this proposal is a request for financial support to continue an investigation of microbial action on marine manganese nodules and terrigenous mineral sulfides, which the principal investigator has been pursuing since 1958. Very intensive work on these materials is being carried on by him, with fruitful results, during the current year, 1961-62, under a provide from the second state of t

Summary of Past Work:\_\_\_\_\_

a. Bacteriology of mineral sulfides.

Attempts were made to evaluate the microbial flora isolable from unsterilized, crushed sulfide minerals by enrichment in mineral solution. The following minerals were studied: alabandite, arsenopyrite, bornite, chalcocite, chalcopyrite, cinnabar, cobaltite, covellite, enargite, galena, marcasite, orpiment, pyrite, pyrrhotite, realgar, and sphalerite. Of these minerals, only cobaltite, enargite, galeta, pyrite, pyrrhotite, realgar, and sphalerite yielded microorganisms. For the most part these organisms were heterotrophic and probably represented contaminants. However, Hyphomicrobium, isolated from realgar, a pink yeast repeatedly isolated

from sphalerite, and <u>Arthrobicter</u>, isolated from cobaltite, galena, pyrrhotite, realgar, and sphalerite may constitute part of a normal flora. The action of any of these organisms with respect to the mineral with which they were found associated remains to be established.

After surface-sterilization, some of the above mineral sulfides, when enriched in mineral solution, have yielded iron-oxidizing autotrophs. These minerals include arsenopyrite, pyrite, pyrrhotite, chalcopyrite, enargite, galena, marcasite, and sphalerite. At least some of the isolated bacterial strains are not restricted to a diet of iron for energy, but can use sulfur or, probably, some other oxidizable metals.

The ability to grow on any of the above sulfide minerals was tested by inoculating surface-sterile samples in oxidizing columns with <u>Ferro-</u> <u>bacillus ferrooxidans</u>, and attempting to recover the organism from effluent fceding solution over a period of two months or more. So far, positive results have been obtained with arsenopyrite, enargite, chalcopyrite, marcasite, galena, pyrite, pyrrhotite, and sphalerite. Negative results have been obtained with alabandite, bornite, cobaltite, covellite, chalcocite, and one sample of galena. Cinnabar, orpiment, and realgar are being currently investigated.

In addition to the foregoing qualitative work, quantitative studies on the rates of oxidation of synthetic  $Cu_2S$  and natural arsenopyrite are presently being undertaken. From these studies it has become clear that synthetic  $Cu_2S$  can be oxidized at least 4x as fast by bacteria than by autoxidation, and that arsenopyrite can be more rapidly oxidized by bacteria than by autoxidation. Results with the latter material are not yet sufficient to establish an exact rate comparison. The precise mech-

anism of bacterial oxidation remains to be established. The work with synthetic  $Cu_2S$  proves, what some other workers seem to doubt, that  $\underline{F}$ . ferrooxidans can oxidize metals other than iron.

b. Manganese Nodules

Oceanographers have felt pretty strongly in the past that the origin and development of manganese nodules in the oceans is attributable to purely physicochemical processes. However

on finding organic nitrogen in nodules, concluded that biological agents were involved in nodule genesis. At his suggestion, the principal investigator attempted to find out if bacteria might play a role in this. He found that bacteria were indeed present in the nodular substance after surface-sterilization (a rough estimate at present is 10<sup>4</sup> per gram). They included Achromobacter, Arthrobacter, Bacillus, Brevibacterium, Staphylococcus, Vibrio, an unidentified rod, and an unidentified coccus. The principal investigator showed in quantitative experiments that nodular substance can adsorb manganous ion-from sea water, and that this adsorption is accelerated by bacteria that grow from the nodular material. The acceleration of manganous ion adsorption is explainable on the basis that the bacteria oxidize the adsorbed manganese, which facilitates further adsorption of manganous manganese. The acceleration requires the presence of peptone, to permit bacterial development. If peptone and glucose are present, mangamese is released from the nodular substance rather than adsorbed, at least in a net effect. Since some nodules were apparently initiated around shark's teeth, ear bones of whales, pumice, etc., in the sea, attempts were made to see if oyster shells can adsorb manganous manganese and thus serve as possible foci of nodules.

It was found that they do adsorb it and that peptone did not stimulate this adsorption (no bacteria were present!). As far as a survey of the literature has gone, these observations with respect to manganese nodules have not been reported before.

-4.

## Pertinent literature:

The early literature dealing with microbial action on minerals has been covered by Alexander (1). A review by Lyalikova summarizes much of the past important work on Thiobacillus ferrooxidans and Ferrobacillus ferrooxidans (2). An intimate association of iron-oxidizing autotrophs with natural mineral sulfides has been indicated by the work of and by that\_of\_Lyalikova (5). Differences of opinion exist between Bryner and Anderson-(6), Malouf and Prater (7), and Ivanov, Nargirvyak, (8) on the other and Stepanov on the one hand, and about a mechanism of mineral sulfide oxidation of chalcopyrite, molybdenite, chalcocite, and sphalerite, for instance. No previous studies on bacteria in manganese nodules has been reported. However, bacterial manganese oxidation and reduction by soil bacteria has been known for some time. An important quantitative study on large-scale bacterial manganese metabolism is that of Mann and Quastel=(9). Descriptions of manganese nodules are given by Murray (10) and Dietz (11). A chemical and physical study of nodules was made by Buser and Gruetter (12). The finding of organic nitrogen in nodules was first reported by Graham (13) and Graham and Cooper (14), who also suggested a biological origin of the nodules on this basis.

A STUDY OF MINERAL=TRANSFORMING MICROURGANISMS

133-3

Purpose:

4. Yes)

The project proposed herein is intended to provide information on the microbiological participation in mineral transformation. Only scanty knowledge is available in this field at the present time. The work will consider ooth ecological and physiological aspects of the problem. The findings should be a valuable contribution to fundamental knowledge in microbiology, geology, and allied fields. They should also be a valuable contribution to practical knowledge in these areas because ways may be shown to harness some of these microorganisms to do useful work for Man, such as aiding in the conversion of minerals of <u>low economic value into</u> substances of high economic value. Ways may also be shown for growing food from minerals by a non-photosynthetic process, because some bacteria, already known to attack certain minerals, can dhange=602 into organic matter with the energy which they derive from the oxidation of the minerale, (1). This organic matter may then in turn serve as food for other microorganisms which may be used directly or indirectly as food for Man.

From preliminary invectigations by the senior investigator (2), it has become apparent that mineral-transforming microorganisms are intimately associated with various types of minerals. The proposed research is designed to follow up the leads from this earlier work to delineate clearly the environmental and functional

			methods.		
					fron
					soils by
					percolation
					effluent
					e selective
			s-iron broth (3		
		thiosulfate b	oroth (4), nutri	ent broth, etc.	

Microbial enrichments will also be derived from flask cultures prepared by overlaying crushed ore, other mineral substances; and soils with a nutrient salt solution. Microbial enrichments of drainage waters from mineral deposits will be made oy inoculating suitable volumes into the various selective media already cited. Other enrichment methods may be used as they become appropriate. The ores and other mineral substances will be used before and after surface sterilization.

Pure cultures from the various enrichments will be prepared by streaking on solidified inorganic and organic media, whenever possible. In cases where neither highly purified agar or silica gels work, a dilution technique using selective liquid media may be employed. Culture purity will be established by appropriate morphological and cultural observations. Attempts at establishing the taxonomic identity of the isolates will be made.

b) A study of the over-all-chemical activity on various mineral substances by enrichment cultures and pure cultures. The over-all chemical activity will be studied with enrichment cultures and pure cultures acting on mineral substances of known composition. In these studies, dualitative and quantitative measurements will be made on substrate decomposition, product accumulation, changes in tituatable acidity, pH, redox potential, consumption of CO<sub>2</sub>, O<sub>2</sub>, and organic matter, if any. A comparison of activities in enrichment cultures with activities in <u>pure cultures on identical media will reveal whether</u> the cooperation of more than one mic**voorganism is** required for a given transformation.

133-38

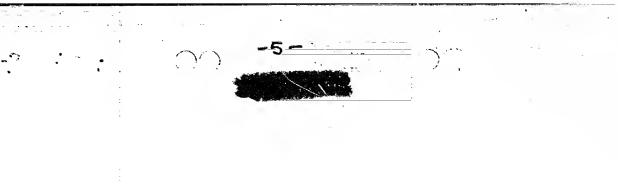

c) A study of the mechanisms of action on various mineral substances by microbial isolates.

The mechanism of action on various mineral substrates by pure cultures will be investigated by the use of standard chemical, biochemical, and physiological techniques. The experimental approach will include a quantitative analysis of the action on pure mineral compounds, on soluble forms of the cations and anions of which the respective minerals are composed, and on the theoretically possible intermediates of metabolism. Such information will be required for the formulation of a scheme that would explain the possible over-all chemical reaction observed.

A STUDY OF MINERAL-THANSFORMANG MICHOORGANISMS 133-38

21 - C

A number of reports exist in the literature about microorganisms which seem to be associated with processes of mineral transformation. In many instances, the function which these microorganisms play is not known or has been misinterpreted. The following is addiscussion of some reports on microbial action on minerals common in nature. Sulfur:

An inspection of the 7th edition of Bergey's Manual of Determinative Bacteriology reveals that bacteria have been associated in the past with sulfur oxidations and reductions (1,2). The Thiobacteriaceae include members that have been shown to oxidize various forms of sulfur more reduced than sulfate. These organisms are all obligately or facultatively chemoautotrophic. Most are strictly aerobic, except for Thiobacillus denitrificans, which is facultative. Photosynthetic bacteria, belonging to the Ghlorobacteriaceae and the Thiorhodaceae, have been shown to use inorganic sulfur compounds other than sulfate as reductants in photosynthesis. More questionable is the association of nigher bacteria, the Beggiatoaceae and Achromataceae, with sulfur oxidation. Their association with sulfur is largely based on the observation of intracellular deposition of sulfur granules. Faust and Wolfe have recently shown that Beggiatoa alba's activity on sulfur is restricted if not absent, at least in laboratory culture (3). The nabitats of all these pacteria seem to be soil, fresh and marine waters, and sulfur deposits (4). In at least one instance, a sulfur oxidizer has been isolated from coprolite rock (fossil dung) of the Triassic period (1). A fairly recent review of the sulfur bacteria is contained in (5),

Sulfur reduction has been most extensively studied in relation to the activities of <u>Desulfoviorio</u> desulfuricans of the Spirillaceae. Members of this genus reduce sulfates, thiosulfates, sulfites, etc. to hydrogen sulfide under anaerobic conditions. The habitats of these bacteria include soil, sewage, water, oil-bearing strata, etc. Uptodate discussions of the physiology of these bacteria are contained in (6,7). Iron compounds:

 $\bigcirc \bigcirc$ 

-2-

132-3

The interaction of bacteria with iron compounds was observed as early as 1888 (8). In this work, a sheathed bacterium, Leptothrix, was observed to deposit ferric hydroxide in its sheath. It was believed that the organism was chemoautotrophic, getting its energy for carbon dioxide assimilation from the oxidation of ferrous ipon. However, the chemoautotrophic nature or this organism and many other iron bacteria has not been satisfactorily proven in the light of our present understanding of chemosutotrophy. At present it seems more likely that the sheathed bacteria (Chlamydobacteriaceae, Crenotnticaceae) deposit ferric hydroxide from ferruginous waters in their sheaths without metabolic mediation. The same kind of ferric hydroxide deposition is believed to take place in the case of the stalked bacteria (Caulobacteriaceae). In their case, too, it is at present questioned whether chemoautotrophy accounts for the ferric hydroxide deposition. the one exception in this instance may be Gallionella ferruginea (9). Among encapsulated bacteria (Siderocapsaceae), the majority of the bacteria seem to deposit ferric hydroxide in their capsules or outer cell=surfaces by non-chemoautotrophic means. Only the genus Ferrobacillus in this family oxidizes ferrous iron by strictly chemoautotrophic means, at a very acid pH (10). This genus is probably related to the Thiobacteriaceae (1). The

reported habitat for all these bacteria is iron-bearing water. Certain iron ores also seem to centain them; (11).

-3-

Various common bacteria are able to precipitate iron from organic salt combination (12). Such genera as <u>Escherichia</u>. <u>Aerobacter</u>, <u>Pseudomonas</u>, <u>Bacillus</u>, etc. are able to bring this about by digesting away the organic portion of the salt. Actinomycetes of the genera <u>Nocardia and Streptomyces</u> can also carry out such activity.

133-3X

Ferric iron reduction may be promoted directly or indirectly by microbial agents. The indirect effect is probably the more common, taking place in a reducing environment at acid pH created by various bacteria. However, Bacillus circulans can reduce ferric iron through direct metabolic interaction (13). Iron sulfides may be precipitated through the formation of hydrogen sulfide by sulfate reducers or by release of hydrogen sulfide from organic sulfur compounds by various common bacteria. Manganese compounds:

deposition Manganese/has been associated with many of the Siderocapsaceae which are also associated with iron deposition. In general, evidence is lacking for metabolic dependence of this manganese precipitation (1,2), although Beijerinck reported long ago that some true bacteria and fungi from soil could oxidize manganese sulfate or manganese carbonate (heterotrophically) (14,15). Some bacteria seem to be able to reduce manganese dioxide under conditions where this compound can act as an electron acceptor in place of oxygen. Quastel and Scholefield (16) reported on such a process. Chemoautowrophic manganese oxidation has been reported by Prave(17) and by Sartory and Meyer (18), but confirmation of these observations is required.

#### Copper compounds:

: e

Transformation of copper compounds has been reported by Ciferri and Scaramuzzi (19), Hurwitz (20), and Bryner and Jameson (21). Only in the last of these three reports does evidence exist that enzymatic action on copper compounds is involved; in fact, the bacteria in that report are described as chemoautotrophs allied to the chemoautotrophic iron oxidizers. In the first\_two\_reports, metabolic end-products are held responsible for the transformation of insoluble copper compounds. <u>Molybdenum compounds</u>:

-5-

133-38

An organism related to the chemoautotrophic iron-oxidizers has been discovered to be able to oxidize the mineral molybdenite (MoS<sub>2</sub>) (22). The products of its action on this mineral are sulfate and molybdic acid. Nothing further seems to be known about this transformation.

#### Silicates:

Bacillus siliceus has been reported to release potassium from a bound state in aluminum silicates when the organism is growing in a potassium deficient environment (23). Aspergillus niger has also been reported to decompose clay minerals to satisfy its potassium requirements (24). Acid formation and its subsequent action on the minerals probably accounts for the potassium release. The acids may include carbonic, organic, nitric, and sulfuric acids.

#### Conclusion:

This literature review is intended to bring out the fact that microorganisms may bring about mineral transformation in two ways; by direct enzymatic interaction, usually causing oxidation or reduction; or by indirect action through the production of environmental conditions which promote transformations\_through the production of environmental conditions which promote transformations through chemical reactions of a purely non-biological nature. It is the first type of transformation which will be stressed in the proposed work.

In spite of the impression that certain problems of micropial mineral transformation have been resolved, more extensive inspection of the pertinent literature reveals contradictions. Three examples bearing on the problem of facorobial action in mineral sulfide transformation will be cited for illustration.

Leathen et al. (25) claimed that they could observe Ferrobacillus ferrooxidans to oxidize marcasite but not pyrite. Both these minerals have the same composition (FeS<sub>2</sub>). They attributed this difference in action of the basteria to a difference in crystal structure between marcasite and pyrite. Yet, Bryner <u>et al.</u> (21) and **Constitution** could obtain growth on pyrite by <u>F. ferrooxidans or a closely related organism</u>.

A second unresolved problem concerns the oxidation of molybdenite (21). In this work, an organism related to <u>F. ferrooxidans</u> oxidized the mineral to sulfate and molyodic acid. The workers assumed that oxidation of the sulfur components of the mineral accounted for this reaction. They overlooked completely the fact that molyodenum had itself undergone an oxidation. The question thus arises whether the bacteria were directly responsible for molybdenum oxidation.

A third ivem or conflicting information concerns the reported ability of <u>F. ferrooxidans to grow on media solidified</u> with agar (26). Bryner and Jameson could not confirm this observation (27). It is thus clear that even on those microorganisms for which extensive information is available concerning their role in mineral transformation, further Wrk is needed to clarify various points of conflicting information.
